

2.2 Construction stage

It relates to transport the produced steel bars and fresh concrete to the construction site and cast concrete using pump and vibrator, in which the evaluation of CO₂ emission during transportation process adopts the same method as above. The method of calculating CO₂ emitted by casting concrete is similar to the production of fresh concrete. Utilizing the energy consumption of the pump and vibrator during casting fresh concrete computes the CO₂ emission. During construction stage, the CO₂ emitted by using pump and vibrator to cast concrete can be referenced as the following Table4.

Table 4. The basic unit of CO₂ emission during construction stage

Item	Unit	CO ₂ -kg/m ³	Reference
Pump	m ³	0.074	Institute for Diversification and Energy Saving
Vibrator	m ^{3*}	0.04	

2.3 Use stage

In the use stage, due to CO₂ or other aggressive substances penetrate into concrete and react with Ca(OH)₂, which is the main hydration production of cement, cause the steel embedded corrosion and concrete structure destroy. Therefore, CO₂ will be emitted during replace some damaged concrete elements. In this study, comparing the CO₂ capture, the problem of concrete elements destroys can be ignored. Thus, in the life cycle of concrete elements, the CO₂ absorption will be considered during the use stage, not the CO₂ emission.

2.4 Demolition stage

When concrete structure gets to the using life, concrete structure and elements need to be demolished. The prophase of demolition stage, CO₂ emission stems from using the dissolution equipment; the late demolition stage, CO₂ emission involves the waste transportation, recycled using as an aggregate in the production new concrete and so on. The CO₂ emitted by waste transportation can adopt the same method as the raw materials transportation stage, the calculation during demolition and crushing process can be referenced as the following Table5.

Table 5. The basic unit of CO₂ emission during demolition stage

Item	Unit	CO ₂ -kg/m ³	Reference
Demolition	m ³	3.81	Institute for Diversification and Energy Saving
Crushing	m ^{3*}	0.59	

3 Development of concrete structure life-cycle CO₂ absorption evaluation method

Because CO₂, due to react with Ca(OH)₂ existing in cement hydration productions, can be captured during the use stage and demolition stage, CO₂ absorption should be considered as evaluate the CO₂ emission. About the evaluation method of CO₂ absorption, many scholars present some different methods, in which the common using method is utilize the carbonation depth multiply the exposed surface areas of concrete. Pade and Guimaraes (2007) and Doodoo et al. (2009) used the following equation to calculate CO₂ absorption based on the predictive models of Fick's first law of diffusion and the life of concrete structure.

$$C_A = x \times M_c \times f_{CaO} \times r_{CaO} \times A \times m \quad (5)$$

$$x = k\sqrt{t}$$

Where C_A indicates the total CO₂ absorption of concrete, x expresses the carbonation depth, M_c is the quantity of OPC per cubic meter of concrete, f_{CaO} is the amount of CaO content in Portland cement CaO (assumed to be 0.65), r_{CaO} is the proportion of CaO can be carbonated (assumed to be 0.75, Lagerblad 2005), A is the exposed surface area of concrete, m is the chemical molar fraction (CO₂/CaO equate to 0.79), k is the carbonation rate coefficient and t indicates the years of service life. According to the EHE code (Fomento 2008), the service life can be calculated by classifying two sections as following equation (6).

$$t = \left(\frac{c_d}{k} \right)^2 + \frac{80 \times c_d}{d_s \times v_c} \quad (6)$$

Where c_d is the protective layer thickness of concrete (mm), d_s is the diameter of steel bar (mm), v_c is the corrosion speed (um/year).

4. Study on the case of CO₂ emission-absorption of concrete structure

4.1 Overview

In this study, one RC plate, beam, column and shear-wall were taken to research during the lifetime of concrete structure, respectively. The compressive strength value is same (25MPa) for the four elements, as well as the concrete mix, dimension and steel reinforcement of three kinds of elements were provided in Table6 and Table7. To obtain the CO₂ emission during life-cycle of three elements, assuming the distance and type of freight vehicle indicates in Table8, in which Fresh Concrete denotes the distance from the ready-mixed concrete plant to the construction site, Demolition Concrete denotes the distance from the construction site to Waste disposal Center and others indicate from its material producer to the ready-mixed concrete plant.

4.2 Evaluation CO₂ emission of concrete structure

Using the method in section2 introduction, CO₂ emission of concrete structure can be evaluated. The detailed calculation process indicates Table9, and the final result was given in the Table10.

Table 9 Examples for evaluation CO₂ emission of deferent stages (kg/element)

Item(unit: Element)	Material Production Stage							D km Distance	Transportation Stage

4.3 Evaluation CO₂ absorption of concrete structure

During the process of calculation CO₂ absorption of life-cycle concrete, combined with the actual situation, two surface area of plate, three surface area of beam and four surface area of column are considered to uptake CO₂ existing in ambient air. According to the EHE code, assuming the carbonation rate coefficient k equal to $4.72\text{mm/year}^{0.5}$, and the corrosion speed rate equal to $2\mu\text{m/year}$. The years of service life, using the equation (6), for plate, beam, column and shear-wall is 84.62 year, 115.40year, 100.40year and 84.62 year, respectively. Obviously, because the protective layer thickness of plate is thinner than beam and column, the service life for plate is shorter than that beam and column. CO₂ capture depends on the service life and exposed surface area, according to the above introduction and just computed service life, the CO₂ absorption can be calculated by using equation (5), and the results present in the Table11.

Table11 Examples for evaluation CO₂ absorption of deferent concrete elements (kg)

Item	Plate	Beam	Column	Shear-wall
use stage	14.72	4.94	6.41	7.36
Demolition stage	16.42	5.51	7.15	8.21
Sum	31.14	10.45	13.56	15.57

4.4 Assessment results and analysis

Drawing the CO₂ emissions during every stage of concrete life in a picture, as

shown in Figure 2, we will find the max emission appears in the production stage, especially in the material production stage, above 70% emission happens in this stage. Additionally, because the dimension of four concrete elements is different, in order to make the results comparable, changing the CO₂ absorption and emission of these four elements into the same volume, as illustrated in Table 12. Simultaneously considering CO₂ emission and absorption, the result of four concrete elements was drawn in a same picture as the Figure 3 shown. Observing the results, we can get the total emission of CO₂ per unit volume is same for different concrete elements; however, the total absorption of CO₂ per unit volume is totally different. The reason for this result is that the exposed surface area of concrete plate is the larger, and the capture of CO₂ is the most in the three elements. Therefore, when we assess the emission CO₂ of life-cycle concrete, concrete carbonation and structural element types must be considered. Using this regular to concrete structures with different structural types, such as frame structures and shear-wall structures, we can deduce that one frame structure, in the case of the same building area, will emit more CO₂ than that of one shear-wall structure.

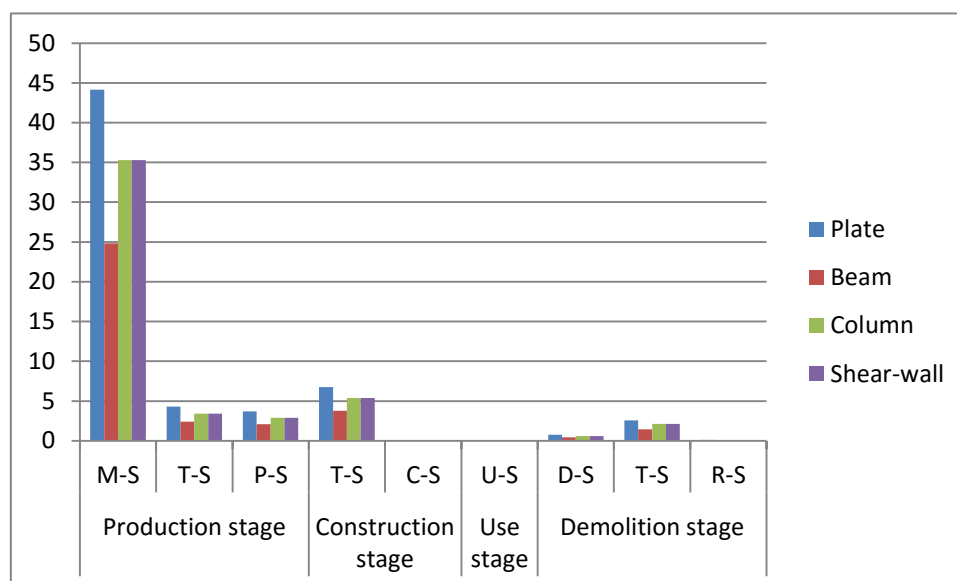

Fig. 2 CO₂ emissions during every stage of concrete life

Table 12 CO₂ emission and absorption per unit volume of each concrete element (kg/m³)

Item	Plate	Beam	Column	Shear-wall
Emission	311.78	311.80	311.83	311.83
Absorption	155.7	92.89	84.75	97.31
Total	156.08	218.91	227.08	214.52

5. Conclusions

In this study, the CO₂ emission and uptake in production stage, construction stage, use stage, and demolition stage are calculated; meanwhile, the influences of structural element types, shapes, and sizes on CO₂ uptake performance are clarified. Under the specific cases adopted in this study, the following conclusions can be drawn:

- In the life-cycle of concrete structure, the CO₂ emission and absorption will happen, regardless the production stage, construction stage, use stage, and demolition stage. Generally, the emission main happen in the production stage, construction stage and demolition stage, especially the production stage, and the absorption main happen in the use stage and demolition stage.
- When the reinforced steel bars did not be considered, the total emission of CO₂ per unit volume is same for different concrete elements; however, if concrete carbonation was considered, the result is totally different. The larger exposed surface area of concrete, the more CO₂ emission of concrete.
- For concrete structures with different structural types, because the relative ratios for different structural element are different, the CO₂ uptake ability is also different. The more areas of plate or shear wall, the less CO₂ emission of concrete structure.
